Case Report: Locally Advanced Colorectal Cancer Diagnosed by Pathology From Abdominal Wall Necrotic Tissue

ABSTRACT
Colon cancer can present with variable clinical manifestations. An unusual finding is the direct dissemination of colon adenocarcinoma through the abdominal wall and skin.

We present a rare case of complicated diverticulitis with abscess formation that demonstrates diagnosis of colonic adenocarcinoma from necrotic skin tissue upon debridement.

In the modern world of widespread use of colonoscopy screening, the initial diagnosis of colon cancer is declining. This particular case, however, illustrates the value of maintaining a high index of suspicion in patients with diverticulitis complicated by abscess formation.

Keywords: Locally advanced colorectal cancer, Necrotic Tissue, Pathology, Diverticulitis, Abscess

Introduction
Malignant cutaneous infiltration has been described in 0.7-9.0% of patients with visceral neoplasms (1–4) and in 5.8% of colon cancer cases (5). While abdominal computed tomography (CT) is effective in diagnosing acute uncomplicated diverticulitis, it can be difficult to differentiate it from underlying neoplasms and inflammatory conditions in diverticulitis complicated with perforation, fistulation and abscess formation (6). We report a case of a patient who originally presented with acute diverticulitis and abdominal wall abscess and was subsequently diagnosed with colon cancer based on a biopsy from necrotic skin tissue debridement. Although such cases are uncommon, our findings indicate that malignant tumors should be considered during work-up of complicated diverticular diseases.

Cases and Methods
65 year old white man, former smoker, known to have sigmoid diverticulosis and prior history of diverticulitis with negative family history of malignancy, initially presented in June 2020, to the emergency of another hospital for worsening left lower quadrant abdominal pain of 1 week duration associated with diarrhea and episodes of fever.

Initial abdomen pelvis CT scan with intravenous (IV) contrast, showed sigmoid diverticulitis with microperforation and suspected early abscess formation of 2.3 cm in the anterior wall of the proximal sigmoid. Patient was admitted for management with “Non Per Os” status, IV antibiotic therapy and fluids with a planned diagnostic colonoscopy in 6-8 weeks after resolution of the diverticulitis. His symptoms improved with medical therapy and labs showed decrease in leukocytosis and Carcinoembryonic Antigen (CEA) <0.5 ng/ml (Normal range: 0-2.5 ng/ml). A CT guided abscess drainage and paracentesis confirmed negative cell count but the pyogenic culture grew P. aeruginosa and E.coli.

An interval CT abdomen pelvis demonstrated proximal sigmoid colon wall thickening with persistent peridiverticu-lar abscess of 2.7 cm and new rectus sheath hematoma and edema of abdominal wall.

Six weeks after discharge, the patient presented again to the emergency with a picture of sepsis and cellulitis. He had acute severe generalized abdominal pain and a new 10x20 cm area of erythema underneath his umbilicus. CT abdomen pelvis revealed progressive inflammatory process in the lower abdomen and anterior extension into the abdominal wall with now large anterior abdominal wall...
abscess and connection to the sigmoid colon. An emergent CT guided drainage offered no significant clinical improvement. A repeat CT demonstrated decreased abdominal wall collection but a continued focal masslike wall thickening of the sigmoid concerning of neoplasm. A CT guided paracentesis was negative for malignancy in the ascitic fluid. However, the abscess culture grew vancomycin re-sistant enterococcus (VRE) and the histologic studies of pelvic hematoma aspiration was highly suspicious for ade-nocarcinoma.

Another CT, confirmed extensive mass involving the sigmoid over 11 cm length producing stricture and proximal colonic distension, with extension to the abdominal wall. After 19 days, the patient was instructed to follow up for ambulatory surgical evaluation.

One week after his second discharge, the patient presented to the emergency with increasing pain and erythema in midline lower anterior abdominal wall. His review of systems confirmed 20 pounds weight loss over the last 3 months after the onset of his symptoms with no fever or blood in stools. His vitals were stable. Physical exam showed distended abdomen, purulent discharge from draining site and 10x5 cm area of redness, swelling and indura-tion inferior to the umbilicus with no signs of peritonitis. Labs were negative for leucocytosis or acute drop in hem-atocrit. A CT abdomen pelvis with contrast revealed a large 7 cm thick walled complex cystic mass from the sigmoid colon demonstrating fistulous communication with the lower anterior abdominal wall, related to a chronic pericolonic diverticular abscess with subcutaneous emphysema, partial bowel obstruction at the level of sigmoid and moderate ascites. Patient was urgently transferred to the operating room for incision and drainage of abdominal wall abscess with debridement of necrotic tissue. The pyogenic culture grew Enterococcus gallinarum, faecium and VRE. The pathology readings from the abdominal wall necrotic tissue confirmed invasive moderately differentiated adenocarcinoma of colon (Figure 4).

Hospital course was prolonged over 12 days during which the patient significantly improved. He was discharged with a central line to continue IV antibiotics and wound dressing at a specialized center. On a follow up phone call, the patient was recovering well. He underwent en bloc resection of the colon tumor with good prog nostication. Table 1 represents the timeline of different emergency department presentations and hospital admissions.

Discussion

Colorectal cancer (CRC) is currently the 3rd leading cause of death among men and women in the United States. In 2020, there will be an estimated 104,610 new cases of colon cancer diagnosed in the U.S. including 53,000 deaths. Although most CRC’s are diagnosed after symptoms onset (70-90%), many CRC in the early stages are found in asymptomatic individuals. Following a diagnosis of diverticulitis, colonoscopy should be performed to rule out underlying malignancy, which can be seen in up to 1.6% of cases (7). Presentation of acute diverticulitis resulting from malignancy with abdominal wall abscess and cutaneous skin involvement is even more rare. Locally advanced colon cancer that spreads along tissue planes may result in formation of abscesses, seen only 0.3-4% of the time (8). CT scan is usually the diagnostic tool used to confirm the presence of diverticulitis in the context of the appropriate symptoms. CT scan can also access for any abscess formation or masses. This case report demonstrates the for-mation of an abdominal wall abscess over the course of a couple months with fistulous connection from the sigmoid colon to the abdominal wall with confirmation of adenocarcinoma from necrotic skin tissue debridement. malignant cutaneous infiltration has been described in 0.7-9% of patients with visceral neoplasms and in 5.8% of colon cancer cases. In two recent meta-analyses, CRC was detected by colonoscopy in 8.3-10.8% of patients with compli-cated diverticulitis, but only in 0.5-0.7% of those with uncomplicated diverticulitis (9). This emphasizes the importance of colonoscopy following an episode of uncomplicated diverticulitis as outlined by the American Society of Colon and Rectal Surgeons (ASCRS) (10). En bloc resection in cases of cutaneous involvement is the treatment of choice.
Clinical Presentation

First presentation and hospital admission
6/5/2020 till 6/12/20 (8 days)

Second admission
7/25/20 till 8/12/20 (19 days)

Third admission (Our hospital)
8/20/20 till 8/31/20 (12 days)

Clinical Presentation

Left lower quadrant abdominal pain of 1 week duration associated with diarrhea and episodes of fever

Acute severe generalized abdominal pain, cellulitis under the umbilicus and sepsis

- Increasing pain and erythema in midline lower anterior abdominal wall
- 20 pounds weight loss over the last 3 months after the onset of his symptoms
- Physical exam: distended abdomen, purulent discharge from draining site, worsening cellulitis

Diagnostic Assessment

- Abdomen pelvis CT scan with IV contrast: sigmoid diverticulitis with micropuncture and suspected early abscess formation of 2.3 cm
- CT guided abscess drain-age and paracentesis: negative cell count, pyogenic culture grew P. aeruginosa and E. coli
- CEA < 0.5 ng/ml

- CT abdomen pelvis: progressive inflammatory process in the lower abdomen and anterior extension into the abdominal wall with large anterior abdominal wall abscess and connection to the sigmoid colon
- CT guided paracentesis: negative for malignancy in the ascitic fluid
- Abscess culture grew VRE
- Histologic studies of pelvic hematoma aspiration: highly suspicious for adenocarcinoma

Therapeutic Interventions

Intravenous antibiotics

- Emergent CT guided drainage and drain placement
- Intravenous antibiotics

- Intravenous antibiotics and debridement site wound care
- En bloc resection of the colon tumor

Table 1. Timeline of different emergency department presentations and hospital admissions
Conclusion
Malignant skin invasion has been identified in a limited portion of cases of colon cancer. Abdominal computed tomography can be unsatisfactory to separate acute complicated diverticulitis from existing neoplasms. The case we are discussing is a man with acute diverticulitis and abdominal wall abscess, who was eventually diagnosed with colon cancer on the basis of necrotic skin tissue debridement biopsy. While such cases are unlikely, our findings stress the significance of colonoscopy after a diverticulitis episode to screen out colon cancer.
